(Received )

In small vessels blood is usually treated as a Newtonian fluid down to diameters of about 200 µm. We investigate the flow of red blood cell (RBC) suspensions driven through small tubes (diameters 10 – 150 µm) in the range marking the transition from arterioles and venules to the largest capillary vessels. The results of the simulations combined with previous simulations of uniform shear flow and experimental data show that for diameters less than about 100 µm the suspension’s stress cannot be described as a continuum, even a heterogeneous one. We employ the Dissipative Particle Dynamics (DPD) model, which has been successfully used to predict human blood bulk viscosity in homogeneous shear flow (Fedosov et al. 2011). In tube flow the cross-stream stress gradient induces an inhomogeneous distribution of RBCs featuring a centerline cell density peak, and a cell-free layer (CFL) next to the wall. For a neutrally buoyant suspension the imposed linear shear-stress distribution together with the differentiable velocity distribution allow the calculation of the local viscosity across the tube section. The viscosity across the section as a function of the strain rate is found to be essentially independent of tube size for the larger diameters and is determined by the local hematocrit (H) and shear rate. Other RBC properties such as asphericity, deformation, and cell-flow orientation exhibit similar dependence for the larger tube diameters. As the tube size decreases below about 100 µm in diameter, the viscosity in the central region departs from the large-tube similarity function of the shear rate, since H increases significantly towards the centerline. The dependence of shear stress on tube size, in addition to the expected local shear rate and local hematocrit, implies that blood flow in small tubes cannot be described as a heterogeneous continuum. Based on the analysis of the DPD simulations and on available experimental results, we propose a simple velocity-slip model that can be used in conjunction with continuum based simulations.

Key words: apparent viscosity, cell free layer, dissipative particle dynamics, microcirculation

1. Introduction

In this work the flow of red blood cell (RBC) suspensions in small tubes is investigated by means of Dissipative Particle Dynamics (DPD) simulations, and where possible, the results are compared to available experimental data from the literature. The modeled

† Email address for correspondence: George_Karniadakis@brown.edu
RBCs have previously been well-characterized with a number of single-cell tests (Fedosov et al. 2010a, c), and in plane Couette-flow simulations their suspensions have yielded non-Newtonian viscosities (Fedosov et al. 2011) in excellent agreement with in vitro viscosities of both whole blood and washed erythrocyte suspensions (ES) measured in three different laboratories (Merrill et al. 1963; Chien et al. 1966; Skalak et al. 1981). As expected, the concentration of cells or the hematocrit ($H$) across the gap in the simulation of plane Couette flow was found to be uniform. The cross-stream stress gradient in Poiseuille flow is known, for example (Moyers-Gonzalez & Owens 2010), to give rise to migration across the streamlines for suspended particles of any kind, the magnitude of the effect being dependent on the particle-to-channel size ratio. For fully developed flow in circular tubes the main consequence of migration is the formation of a cell-free layer (CFL) at the wall and a concentration peak at the centerline. Analytical approaches (Sharan & Popel 2001) have attempted to model this effect as a two-phase flow consisting of Newtonian fluid (plasma) in the CFL and in the rest of the cross-section a non-Newtonian suspension spatially uniform in $H$.

The main objective of this work is to investigate whether the assumptions built into such models of blood flow in small tubes are supported by results from the simulations of our multiscale model of blood suspensions. The tube flows of these suspensions (Fedosov et al. 2010d) are expensive to simulate, and therefore it is desirable to know when simplified approaches are feasible. As the tube size is reduced toward the RBC diameter the CFL becomes the dominant feature, and the assumption of a core of homogeneous flow will become increasingly tenuous. Hence our goal is to determine the effective range of such approximations.

The paper is organized as follows. In section 2 we analyze our simulation data with plots of the distributions of variables across the tube section. In section 3 we investigate the scaling of derived variables, such as viscosity, to uncover the way in which these suspension flows change as the tube diameter decreases. We also use dimensional analysis to examine the dimensional flow-resistance correlations of Pries et al. (1992), which suggest that the apparent viscosity of blood relative to the plasma viscosity is essentially independent of the driving pressure gradient. We also develop a simple velocity-slip model that predicts the velocity profile in tubes from 10 microns and above and can be used in conjunction with continuum based simulations. We conclude in section 4 with a brief summary.

2. Simulation results

In this section simulation results for blood flow in tubes with diameters between 10 and 150 $\mu$m are presented. We have used the DPD method (see appendix) for the blood flow simulations and employed the methods of Fedosov et al. (2010a) and Fedosov et al. (2011) to model single RBCs and their suspensions. The steady tube flow simulations were carried out with the specification of: 1) the driving force $f$ per unit mass applied to each DPD particle, which is equivalent to a constant pressure gradient; 2) the tube radius $R$; 3) the suspending solvent viscosity $\mu$ and its density $\rho$; and 4) the tube hematocrit $H^T$ (RBC volume fraction), a RBC concentration measure. We define two important integrals to evaluate the tube hematocrit $H^T$ and the discharge hematocrit $H^D$ from the local hematocrit $H(r)$ and velocity $u(r)$ distributions

$$\pi R^2 H^T = 2\pi \int_0^R H(r) r dr, \quad \pi R^2 U H^D = 2\pi \int_0^R H(r) u(r) r dr,$$

(2.1)
where \( U = \frac{2}{R^2} \frac{\int_0^R u(r)rdr}{\Delta P R} \) is the bulk velocity. Both of these average hematocrits are experimentally measurable. In steady flow experiments \( H^D \) is equal to the specified feed value. After stopping the flow the tube hematocrit \( H^T \) can be measured by centrifugation of the suspension within the tube, which is accurate for sufficiently long tubes. Thus, in experiments \( H^D \) is normally specified, and \( H^T \) is measured. In simulations, \( H^T \) is specified by introduction of the necessary number of RBCs into the tubular computational volume, while \( H^D \) must be derived from the output. We also define a pseudo-shear rate (or an average shear rate) of the flow as \( \dot{\gamma} = \frac{U}{(2R)} \), which serves as a characteristic of the flow strength.

The modeled cells are suspended in the solvent as neutrally buoyant bodies. Most of the results of this paper deal with unaggregated suspensions of healthy RBCs whose viscoelastic membrane properties have previously been converted by Fedosov et al. (2011) into model parameters, which are held constant in all simulations. For aggregating suspensions inter-cellular adhesive forces must be included in the model; their specification is also identical to that of Fedosov et al. (2011). The DPD simulations of the RBC suspensions in Poiseuille flow yield the continuum field variables calculated as statistical averages of particle variables. These include flow velocity, hematocrit, cell density and orientation, and will be presented as radial distributions across tube sections.

2.1. Velocity and shear rate distributions

Figure 1 shows the axial velocity distribution \( u(r) \). The blue dashed lines are quadratic fits of the numerical data for \( H^T = 0.3 \), and for diameters less than about 50 \( \mu m \) the velocity profiles were found to be markedly non-parabolic. For larger tubes, \( D = 100 \mu m \) and \( D = 150 \mu m \), the profiles are well represented with parabolas, except for the near-wall region, a cell-free layer (CFL), where plasma properties dominate. For illustration we plot the wall values of \( du/dr = \tau_w/\mu = \Delta PR/(2L\mu) \) for \( H^T = 0.3 \) in figure 1 indicated by the cyan dash-dotted lines drawn from the wall. Here, \( \tau_w \) is the wall shear stress which is calculated directly from an imposed pressure drop \( \Delta P \) along the tube length \( L \), since the layer next to the wall is void of RBCs and its viscosity is equal to \( \mu \).
Figure 2. Shear rate distributions for blood flow in tubes of various diameters at $H_T = 0.3$. For $D = 100 \mu m$ the vertical dashed lines indicate: the CFL thickness near the wall, and the limit of the linear portion of the distribution near the centerline. The inset with a big arrow pointing to small values of $r/R$ shows a snapshot of RBCs taken around the tube centerline, while the other inset illustrates RBCs close to the CFL and the arrows inside this inset indicate the direction of local shear flow. Both insets are visualizations from the case $D = 100 \mu m$. The pseudo-shear rates are $\dot{\gamma} = 54.84 \, s^{-1}$ for $D = 20 \mu m$, $\dot{\gamma} = 48.81 \, s^{-1}$ for $D = 40 \mu m$, and $\dot{\gamma} = 41.2 \, s^{-1}$ for $D = 100 \mu m$.

The velocity distributions appear to be very smooth since they reflect the statistical averages over all particles including those of the solvent and cells. This permits the calculation of shear rate profiles, and also of local viscosity from the imposed shear stress distributions (Fedosov et al. 2010b). Figure 2 presents the shear rate distributions for different tube diameters calculated numerically from the velocity data for $H_T = 0.3$. For the $100 \mu m$ tube, except for the core region $r/R < 0.2$, the shear rate is linear up to the CFL boundary. For all tube diameters the shear rate distributions can be roughly divided into three regions: i) a non-Newtonian flow region near the centerline with low shear rates $< 60 \, s^{-1}$, ii) a linear region between the centerline and CFL, and iii) a linear region near the wall indicative of a CFL. For the large tube size ($D = 100 \mu m$), these three regions are very apparent: a non-Newtonian flow near the centerline, followed by a linear region with shear rates up to $250 \, s^{-1}$, and then a nearly linear region within the CFL with large shear rates.

2.2. Local cell density and hematocrit

RBCs in blood flow in tubes or microvessels migrate towards the centerline yielding the CFL next to the wall (Goldsmith et al. 1989; Cokelet & Goldsmith 1991). This leads to a variation in local RBC density and hematocrit affecting the velocity profiles and flow transport. Figure 3 shows snapshots of the blood flow cut near the center of the tube for $D = 40$ and $100 \mu m$. The RBC snapshots qualitatively indicate that the cell density (CD) and hematocrit at the tube center are higher than those away from the centerline. To support this statement we plot local cell-center density and hematocrit for different $H_T$ and $D$ values in figures 4 and 5. For the smallest tube diameter ($10 \mu m$) we observe
Blood Flow in Small Tubes

Figure 3. Central cut-plane snapshots along the tube axis for $D = 40 \, \mu m$ ((a) and (b)), and $100 \, \mu m$ ((c) and (d)) at $H^T = 0.3$. (a) and (c) are the half-tube images, while (b) and (d) are thin slices across the cut. CFL thickness is shown by dashed lines parallel to the walls. The pseudo-shear rates are $\dot{\gamma} = 48.81 \, s^{-1}$ for $D = 40 \, \mu m$ and $\dot{\gamma} = 41.2 \, s^{-1}$ for $D = 100 \, \mu m$.

Figure 4. Radial RBC-density distributions normalized by the mean prescribed density: (a) $D = 10 - 40 \, \mu m$ and (b) $D = 100$ and $150 \, \mu m$ for $H^T = 0.3$ and 0.45. The pseudo-shear rates are $\dot{\gamma} = 54.8, 48.81, 41.2$, and $46.9 \, s^{-1}$ for the cases $D = 10, 20, 40, 100$, and $150 \, \mu m$ at $H^T = 0.3$ and $\dot{\gamma} = 45.84, 52.93, 45.56$, and $31.2 \, s^{-1}$ for the cases $D = 10, 20, 40$, and $100 \, \mu m$ at $H^T = 0.45$.

A significant increase of $H(r)$ in the tube center (figure 5(a)), which reflects crowding of RBCs around the centerline. However, the cell density distributions in figure 4(a) for $D = 10 \, \mu m$ are strikingly different for $H^T = 0.3$ and 0.45. Note that the cell-center distributions contain information about an average RBC structure within the suspension which may occur in the flow. Thus, the pronounced peak in the CD distribution for $D = 10 \, \mu m$ and $H^T = 0.3$ indicates that most RBCs attain a parachute shape and move in trains such that the cell centers are narrowly distributed around the tube centerline.
Figure 5. Local hematocrit distributions normalized by $H^T$: (a) $D = 10 - 40 \, \mu m$ and (b) $D = 100 \, \text{and} \, 150 \, \mu m$ for $H^T = 0.3$ and $0.45$. The pseudo-shear rates are $\tilde{\gamma} = 54.8, 54.84, 48.81, 41.2$, and $36.9 \, s^{-1}$ for the cases $D = 10, 20, 40, 100, \text{and} \, 150 \, \mu m$ at $H^T = 0.3$ and $\tilde{\gamma} = 45.84, 52.93, 45.56, \text{and} \, 31.2 \, s^{-1}$ for the cases $D = 10, 20, 40, \text{and} \, 100 \, \mu m$ at $H^T = 0.45$.

In contrast, the CD distribution for $D = 10 \, \mu m$ and $H^T = 0.45$ shows that a preferred position of the cell centers is between the tube wall and centerline indicating that RBCs flow in the so-called zig-zag mode found in experiments by Gahtgens et al. (1980) and in simulations by McWhirter et al. (2009). For intermediate tube diameters ($20 - 40 \, \mu m$) the main features of the CD distributions (figure 4(a)) are an increase of the cell density around the centerline and a peak next to the CFL region. A larger cell density at the tube center is again due to RBC structure or close packing. At the tube center, shear rates are small allowing for a closer packing of cells, and therefore RBCs are transported downstream within a certain quasi-persistent structure. This is also reflected by the flat plug-like velocity profile of the flow around the tube center in figure 1(a). Also, note that the increase in CD and $H(r)$ around the centerline is much more pronounced for the lower simulated $H^T$ value. However, away from the tube center shear rates increase which leads to cell mixing and any close-packed structure is destroyed. In the region between the center and CFL both CD and $H(r)$ are lower than those in the tube center. Also, within this region the cell suspension appears to be nearly uniform in the radial direction, which is reflected by nearly flat CD and $H(r)$ distributions in figures 4(a) and 5(a). Finally, a peak next to the CFL reflects another property of the flow. It appears that next to the CFL most RBCs are aligned with the flow and form a layer of aligned RBCs. Since RBC centers in this layer have similar radial positions, a peak in the CD distributions is observed. However, this property is virtually absent in the $H(r)$ distributions where the peaks next to the CFL nearly subsidie.

For the larger tubes ($D = 100 \, \text{and} \, 150 \, \mu m$) similar features in the CD and $H(r)$ distributions, as discussed above, are found and shown in figures 4(b) and 5(b). Thus, a central peak gives way to a plateau value close to the bulk $H^T$, while the distributions vanish abruptly as the CFL is approached. In agreement with the results for the small tube diameters, the variations in the CD and $H(r)$ distributions become smaller as $H^T$ is increased.
2.3. RBC deformation and orientation

The profiles of concentration and velocity reflect the changes of shape and orientation of the RBCs as they are transported by the flow. Snapshots of cells in the planes cut along the tube axis are illustrated in figure 3. They provide visual correlations of cell shapes and orientations corresponding to the hematocrit and velocity profiles and show how these characteristics vary across the section. Quantitative analysis of cell shape changes along the radius can be performed using the RBC gyration tensor (Mattice & Suter 1994). We define cell asphericity as follows

\[ A = \frac{\left( (\lambda_1 - \lambda_2)^2 + (\lambda_2 - \lambda_3)^2 + (\lambda_1 - \lambda_3)^2 \right)}{2R_g^4}, \quad R_g^2 = \lambda_1 + \lambda_2 + \lambda_3, \tag{2.2} \]

where \( \lambda_1 \leq \lambda_2 \leq \lambda_3 \) are the eigenvalues of the gyration tensor. While the eigenvalues \( \lambda_i \) characterize cell shapes along the main directions defined as the tensor eigenvectors, cell asphericity shows how far a cell shape departs from a sphere such that \( A = 0 \) for a sphere and \( A = 1 \) for an infinitely-long thin cylinder.

The asphericity distributions are presented in figure 6 for various tube diameters and \( H^T \) values. The horizontal dashed line corresponds to the asphericity of a RBC in equilibrium. The RBC asphericity falls below its equilibrium value at almost all radial positions, except right next to the CFL. This indicates that RBCs tend to deform into a more spherical shape. Moreover, the asphericity distributions for larger tube diameters (\( D > 40-50 \mu m \)) show three distinct regions: i) a centerline region, where \( A \) is nearly constant, ii) the region between the center and CFL, where \( A \) increases monotonically with a nearly constant slope, and iii) \( A \) increases steeply next to the CFL. It is also clear that for large enough \( D \) the function of \( A(r) \) converges to a common curve, and therefore becomes independent of the tube diameter. Next to the CFL, cells are subject to highest shear rates, which lead to their elongation shown in figure 7 by the largest eigenvalue \( \lambda_3 \). The cell elongation distributions show that RBCs are slightly compressed in the center of the tube and become more stretched than in equilibrium at the mid point as we approach the CFL region due to shear rate increase. The \( \lambda_3 \) distributions can be also qualitatively divided into the three regions similarly to the \( A \) distributions above.
Figure 7. The largest eigenvalue ($\lambda_3$) of the RBC gyration tensor for different tube diameters: (a) $H^T = 0.3$ and (b) $H^T = 0.45$. The horizontal dashed line denotes the equilibrium value of $\lambda_3$ equal to approximately 4.77. The pseudo-shear rates are $\dot{\gamma} = 54.8, 54.84, 48.81, 41.2, \text{and} 46.9 \text{ s}^{-1}$ for the cases $D = 10, 20, 40, 100, \text{and} 150 \text{ \mu m}$ at $H^T = 0.3$ and $\dot{\gamma} = 45.84, 52.93, 45.56, \text{and} 31.2 \text{ s}^{-1}$ for the cases $D = 10, 20, 40, \text{and} 100 \text{ \mu m}$ at $H^T = 0.45$.

Figure 8. RBC orientation relative to the shear planes or tube axis for different tube diameters: (a) $H^T = 0.3$ and (b) $H^T = 0.45$. The pseudo-shear rates are $\dot{\gamma} = 54.8, 54.84, 48.81, 41.2, \text{and} 46.9 \text{ s}^{-1}$ for the cases $D = 10, 20, 40, 100, \text{and} 150 \text{ \mu m}$ at $H^T = 0.3$ and $\dot{\gamma} = 45.84, 52.93, 45.56, \text{and} 31.2 \text{ s}^{-1}$ for the cases $D = 10, 20, 40, \text{and} 100 \text{ \mu m}$ at $H^T = 0.45$.

To identify RBC orientation in the tube flow we also plot the cell orientation angle $\theta$ in figure 8, which is calculated as the angle between the cell normal and the tube axis. The cell normal is defined by the eigenvector corresponding to the smallest eigenvalue $\lambda_1$ of the gyration tensor of each cell. The smallest eigenvalue characterizes the RBC thickness in the equilibrium biconcave configuration, while the other two larger eigenvalues correspond to the cell radius. Hence, $\lambda_1$ is a good measure of cell orientation provided cell distortions are not extreme, as might occur in tubes of capillary size with diameters smaller than $8 - 10 \text{ \mu m}$. Cell-orientation angles relative to the shear planes show similarity of orientation.
3. The pseudo-shear rates are $\bar{\dot{\gamma}} = 46.8 \text{ s}^{-1}$ for $D = 20 \mu m$ and $\bar{\dot{\gamma}} = 40.3 \text{ s}^{-1}$ for $D = 40 \mu m$.

for the larger tubes. Except for the smallest tube $D = 10 \mu m$, the orientations are all larger than 45 degrees, the principal direction of the shear rate tensor.

2.4. Effect of RBC aggregation

The existence of interactive adhesive forces between healthy human red blood cells is well-established (Chien et al. 1967). In RBC suspensions undergoing very low deformation rates or in equilibrium, these weak forces induce aggregation of RBCs into structures of stacked discoids or rouleaux which affect the measurable flow properties of the blood (Merrill et al. 1966). In particular, the model of this work (Fedosov et al. 2011) has been used to predict the whole range of experimental values of the Couette viscosity (CV) for both aggregating whole blood and non-aggregating erythrocyte suspensions (ES). As the shear rate decreases the CV of whole blood steeply increases relative to that of ES; in the model this corresponds to the inclusion or exclusion of inter-cellular aggregating forces derived from the Morse potential

$$U_M(r) = D_e \left[ e^{2\beta(r_0-r)} - 2e^{\beta(r_0-r)} \right],$$

where $r$ is the distance between cell-membrane vertices of adjacent cells, $r_0$ and $D_e$ are the zero force distance and well-depth of $U_M(r)$, respectively, while $\beta$ determines the range of interaction. For healthy RBCs in homogeneous Couette flow we previously (Fedosov et al. 2011) determined the Morse parameters to be: $D_e = 0.3$, $r_0 = 0.3$, $\beta = 1.5$ with cut-off distance $r_M = 1.1$. These yield maximum adhesive forces between two cells in the range $3 - 7 \mu N$.

Figure 9 shows the velocity and $H(r)$ profiles for tube diameters $D = 20$ and $40 \mu m$ with attractive inter-cellular forces (dashed lines), and without such forces (solid lines). The $H(r)$ profiles indicate that the effect of adhesion is most pronounced for the smallest tube, $D = 20 \mu m$, is only slight for $D = 40 \mu m$, and the increase of $H^T$ from 0.3 to 0.45 does not alter this response. The velocity profiles are only slightly changed, which suggests that the flow in even larger tubes will be insensitive to normal levels of aggregation. Note that aggregation interactions in whole blood are important for the shear rates below $5 - 10 \text{ s}^{-1}$, while at larger shear rates rouleaux structures are completely dispersed (Merrill et al. 1966; Fedosov et al. 2011). The characteristic shear rates ($\bar{\dot{\gamma}}$) of simulated
blood flows are considerably above that threshold, and therefore RBC aggregation plays a minor role here. For much smaller pseudo-shear rates the effect of RBC aggregation is expected to be more pronounced.

2.5. Cell-free layer thicknesses

Several types of hematocrit or RBC concentration measures can be introduced, for example the tube hematocrit $H_T$ and the discharge hematocrit $H_D$ defined in equation (2.1). The difference $H_D - H_T$ has long been taken as a measure (Fahraeus 1929) of the effect in which a CFL develops at the wall, and becomes more pronounced for smaller tube diameters. Another effect which is directly connected to the thickness of CFL is the Fahraeus-Lindqvist effect (Fahraeus & Lindqvist 1931) that describes a decrease in the apparent blood viscosity with decreasing tube diameter found in experiments of blood flow in glass tubes (Pries et al. 1992).

The cell-free layer thickness $\delta$ is observable in vivo (Pries et al. 1989; Maeda et al. 1996; Kim et al. 2007) and is of interest in any study of cross-stream mass transport of the cells moving within the main flow. Experimentally (Bugliarello & Sevilla 1970; Reinke et al. 1987; Maeda et al. 1996; Kim et al. 2007) $\delta$ is measured by direct observation of the cells near the wall whose radial excursions define an irregular edge varying in time along the streamwise direction. The average edge position is taken to be $\delta$, and Fedosov et al. (2010d) adapted this direct method in their simulations. The following alternative measures of CFL thickness are motivated by boundary layer definitions of concentration thickness,

$$\frac{\delta'}{R} = 2 \int_0^R u(r)(H(r) - H_T)rdr/(R^2 U H_D),$$

$$\frac{\delta''}{R} = 2 \int_0^R (U_m - u(r))(H_T - H(r))rdr/(R^2(U_m - U)H_D),$$

where $U_m$ is the maximum flow velocity. These integrals can be expressed simply in terms of $H_T$ and $H_D$ as,

$$\delta' = R(H_D - H_T)/H_D, \quad \delta'' = \delta'U/(U_m - U).$$

The boundary layer definitions of CFL thickness given above for circular cross-sections are also applicable to non-circular tubes for which the direct method yields $\delta$ as a function varying along the perimeter. If the need is for an average value, then the boundary layer definition has the virtue of simplicity.

Figure 10 shows the relative CFL thicknesses $\delta/R$ using the various definitions above. As expected the relative CFL thickness $\delta/R$ decreases with $D$. The boundary layer definition (equation (2.4)) of $\delta'$ appears to be a relatively good approximation for the CFL thickness, while $\delta''$ is about twice as large as $\delta$. However, $\delta''/2$ can also approximate the CFL thickness very well. The experimental values of Bugliarello & Sevilla (1970) ($H_D = 0.4$ translates into $H_T \approx 0.31$) and of Maeda et al. (1996) in figure 10(a) are quite close to the simulated values. Good agreement is also found for $H_T = 0.45$ in figure 10(b) between several experimental data points (Reinke et al. 1987; Maeda et al. 1996; Kim et al. 2007) and simulated $\delta$ values. The deviation of experimental measurements from the calculated values is most pronounced for in vivo measurements (Maeda et al. 1996; Kim et al. 2007). This may be due to several reasons such as the existence of the glycocalyx layer, inhomogeneous vessel structures (e.g., diameter variations, bifurcations), vessel elasticity, and spatial resolution of the measurements (Pries et al. 1989; Maeda et al. 1996; Kim et al. 2007; Fedosov et al. 2010d).
3. Analysis

3.1. Blood viscosity and its scaling

The volumetric flow rate $Q$ and the bulk velocity $U = Q/\pi R^2$ are derived from the integral of the velocity profile across the tube section. For a neutrally-buoyant suspension, the streamwise component of the steady flow equation of motion in terms of the shear stress $\tau$ can be regarded as being driven by a force $f$ or an equivalent pressure gradient $-\partial p/\partial x$ as follows

$$0 = \frac{1}{r} \partial (r \tau) \partial r + \rho f, \quad f = -\frac{1}{\rho} \frac{\partial p}{\partial x},$$

where its first integral is

$$\tau = \tau_w(r/R), \quad \tau_w = R\rho f/2,$$

and $\tau_w$ is the wall shear stress. The velocity profiles in figure 1 show that as the tube size decreases the velocity curves become less parabolic, i.e. non-Newtonian. In the range $D = 20 - 40 \mu m$ the flow is distinctly non-Newtonian and the hematocrit distributions are correspondingly non-uniform (see figure 5). For $D = 100 - 150 \mu m$, the main flow is nearly parabolic except for the CFL region.

In plane Couette flow the modeled RBC suspensions of this work exhibit non-Newtonian viscosities (Fedosov et al. 2011) dependent on both the shear rate ($\dot{\gamma}$) and $H$ in good agreement with experimental values (Merrill et al. 1963; Chien et al. 1966; Skalak et al. 1981). In previous simulations (Fedosov et al. 2010b) of Poiseuille flow of polymer solutions it was found that the non-Newtonian viscosity as a function of $\dot{\gamma}$ and concentration can be extracted from the profiles of velocity and shear stress. This method contains the local action assumption that stress depends on the local values of $\dot{\gamma}$ and concentration, i.e. the material is assumed to be a continuum locally. For the neutrally-buoyant suspensions of this work the shear stress is prescribed (equation (3.2)), and the viscosity across the section is calculated from $\tau/\dot{\gamma}$ with the shear rate derived from the velocity profiles by numerical differentiation following the method of Fedosov et al. (2010b). Figure 11(a) shows the relative viscosity (the RBC suspension viscosity normalized by the solvent viscosity) as a function of the local shear rate along with the
Figure 11. (a) Relative viscosity (the cell suspension viscosity normalized by the solvent viscosity) versus shear rate for $D = 20, 40, 100, \text{ and } 150 \mu m$ at $HT = 0.3$. Experimental values are shown by symbols. The vertical dashed line gives the position of the CFL for $D = 150 \mu m$. (b) Relative viscosity with respect to the shear rates scaled by their values at the CFL transition points.

Experimental rotational-Couette viscosities of Chien et al. (1966) and Eckmann et al. (2000). The experimental points are plotted with symbols at constant shear rates $5.2$, $52$, $100$, and $200 \text{ s}^{-1}$. From figure 2, the two lowest rates correspond to the nonlinear region near the centerline of the channel, and from figure 5 for $D = 100 − 150 \mu m$, they correspond to approximately $H = 0.5$ and $0.4$, respectively. The two larger shear rates lie in the linear shear-rate region with $H \approx 0.34$. Since the shear rates of figure 11(a) correspond to the shear-rate profile of figure 2, the viscosity can be traced from its low shear-rate value at the centerline as it drops by an order of magnitude to the edge of the CFL, and then drops abruptly to the plasma value. The large viscosity drop across the main flow is counter-intuitive in view of the nearly parabolic velocity profile of figure 1, and the mildly varying $H$ in figure 5. However, the main viscosity drop occurs for shear rates $\dot{\gamma} < 50 \text{ s}^{-1}$ which correspond to the nonlinear region near the tube center.

At the CFL edge the relative viscosity abruptly changes the slope and the viscosity $\eta_{cf}/\mu$ and shear rate $\dot{\gamma}_{cf}$ at the abrupt transition are used as scale factors to produce figure 11(b), where the dimensionless scaled viscosity is plotted as a function of dimensionless scaled shear rate. Table 1 presents various characteristics at the abrupt transition. The fourth column gives the experimental relative apparent-viscosities $\eta_{app}/\mu$ (Pries et al. 1992). They suggest that Poiseuille flow in small tubes yields apparent viscosities which lie between the plasma viscosity and the value at the inner-edge of the CFL, and approach the latter as the relative CFL thickness $\delta/R \to 0$. It will be shown below in figure 13 that the apparent viscosities predicted by the DPD model are in good agreement with the experimental values of $\eta_{app}/\mu$.

The shear rate and viscosity at the abrupt transition in figure 11(a) correspond closely to the position of the CFL thickness $\delta$. Inspection of the relative viscosity curves suggests that they have a degree of similarity which implies that the viscosity is a two-parameter function of the strain rate, and therefore the viscosity curves in figure 11(a) are re-scaled with $\eta_{cf} \text{ and } \dot{\gamma}_{cf}$ and shown in figure 11(b). In the vicinity of $\dot{\gamma}_{cf}$ the scaled curves superpose within numerical accuracy whereas in the central region they separate. For the larger tubes ($D = 100 − 150 \mu m$) this separation of the curves is not significant, but for
the smaller ones the departure is clear. Experimental Couette viscosities, given by the function \( \eta(\dot{\gamma}, H) \), define a similarity viscosity function across the section of the larger tubes in figure 11(a). Moreover, the asphericity, \( \lambda_3 \), and cell-orientation angle distributions presented in figures 6, 7, and 8 show clear similarity for the larger tubes consistent with their viscosities, when plotted against the scaled shear rate. These similarity relations for various blood flow properties can be used in a heterogeneous continuum theory such as proposed by Moyers-Gonzalez & Owens (2010).

The agreement between simulated viscosity distributions and experimental values for larger tube diameters is consistent with the local viscosity in Poiseuille flow being the function \( \eta(\dot{\gamma}, H) \) as that which characterizes spatially homogeneous shear flow. However, the departures of the viscosity distributions from the experiment for the smaller tubes suggest that the continuum assumption may not be valid for tube diameters < 100 \( \mu m \). Thus, the main finding of this work is the quantification of the transition from a continuum to a non-continuum description as tube size decreases. Continuum models of materials, whether homogeneous or heterogeneous, are based on constitutive equations which assume the principle of “local action”, which means that within a material domain the stress is describable in terms of independent variables associated with each material element. The combination of the constitutive equation with the conservation laws results is a system of field equations which hold for every point in the domain, while boundary conditions are imposed on the solutions of the field equations. In the simple case of steady shear flow, where a RBC suspension is homogeneous, the viscosity or the stress are function of the shear rate and \( H \). In contrast, a RBC suspension in Poiseuille flow (e.g. in small vessels) may be very inhomogeneous and figure 11 shows the increasing departure of the relative viscosity from Couette data (Chien \textit{et al}. 1966; Eckmann \textit{et al}. 2000) as tube size decreases. Recall that our model (Fedosov \textit{et al}. 2011) agrees very well with these data in uniform shear flow. This means that for small tubes the local viscosity or stress depends also on tube size, and hence no longer satisfies the principle of local action.

3.2. Velocity distribution in the CFL
The velocity profiles displayed in figure 1 suggest that in the CFL the velocity has an expansion in \( y = R - r \), the distance from the wall,

\[
 u(y) = u_y(0)y + 1/2u_{yy}(0)y^2 + O(y^3),
\]

where \( u_y(0) \) and \( u_{yy}(0) \) are the wall values of the first and second derivatives, respectively. Adjacent to the wall the value of the viscosity \( \mu_w \) is initially assumed to be the plasma

Table 1. Scaling parameters for different tube diameters at \( H^T = 0.3 \) including the shear rate \( \dot{\gamma}_{cf} \) and viscosity \( \eta_{cf}/\mu \) at the CFL edge. The relative apparent viscosity \( \eta_{app}/\mu \) (Pries \textit{et al}. 1992) and the CFL thickness \( \delta \) are also included.
value $\mu$ so that $u_y(0) = \tau_w/\mu$. At the wall the lines tangent to the velocity profiles in figure 1 confirm this assumption for $H^T = 0.3$, but the $H^T = 0.45$ near-wall velocity data seem to differ slightly from tangency. It appears that the effective wall-viscosity can increase beyond the plasma value as the cell packing density increases. In turbulent pipe-flow it has been verified experimentally that the wall viscosity is indeed the fluid’s molecular viscosity, where wall-variables are used to scale $u$ and $y$ such that very near the wall, in the viscous sublayer, they are $O(1)$. For the RBC suspension, wall-variable scaling of equation (3.3) is assumed to be as follows

$$u_+ (y_+, y_{cf}) = y_+ \left(1 + a_2 y_{cf} + O(y_{cf}^2)\right), \quad a_2 = u_{yy}(0)\delta/(2u_y(0)),$$

$$u_+ = u/u_*, \quad y_+ = u_* y/\nu, \quad u_* = \sqrt{\tau_w/\rho}, \quad y_{cf} = y/\delta,$$  

(3.4)

where $\nu = \mu/\rho$ is the solvent kinematic viscosity. In the turbulent pipe-flow, the description of the viscous sublayer beyond the linear term in expansion (3.3) requires the next term to be $O(y^3)$ (Spalding 1961). For the RBC suspension there is no “a priori” theoretical reason to decide the order of the next term, and its scale is unknown. In equation (3.4) only the common linear term is scaled with the wall-variables of turbulent flow, and the CFL thickness $\delta$ is used to scale the terms in parentheses. The validity of this assumption can be tested at constant $H^T$ with a plot of $u_+/y_+$ for each tube size as a function of the single variable $y_{cf}$. Figure 12 shows the plots of $u_+/y_+$ versus $y_{cf}$ for various tube sizes. For $H^T = 0.3$ the $u_+/y_+$ curves come together in the CFL region, and extrapolate to unity at the wall. However for $H^T = 0.45$ extrapolation to the wall yields a wall viscosity about 10% higher than the assumed solvent viscosity. From the plot, the coefficient $a_2$ in expansion (3.4) is approximately $-1/2$, and appears to be independent of tube size. For the larger tubes $u_+/y_+$ is a function of $y_{cf} = y/\delta$ alone up to $y_{cf} \sim O(1)$.

3.3. Dimensional analysis of global resistance variables

The similarities found between the CFL and the laminar sublayer region in turbulent pipe flow suggest that resistance relations between global variables might be described in terms of familiar dimensionless groups. Motivated by turbulent flow in pipes the mean or bulk velocity is scaled with the friction velocity $u_* = \sqrt{\tau_w/\rho}$, which leads to the
Blood Flow in Small Tubes

“friction” Reynolds number $R_+ = Ru_*/\nu$. In turbulent pipe flow $u_*$ and $R_+$ are said to be defined in terms of “wall” variables. However, for suspensions the wall viscosity is an unknown, and at higher volume fractions it may vary from the solvent’s viscosity as was shown above. Tube-size effects investigated in this work require the inclusion of the ratio $S = R/R_{\text{cell}}$ ($R_{\text{cell}}$ is the cell radius) as a relevant dimensionless parameter. Dimensional analysis now suggests the following dimensionless functional relations:

$$U_+ = \frac{U}{u_*} = f_1(R_+, S, H^T), \quad \frac{\delta}{R} = f_2(R_+, S, H^T), \quad \frac{H^D}{H^T} = f_3(R_+, S, H^T), \quad (3.5)$$

where the $f_i(R_+, S, H^T)$ are unknown functions. It is useful to recall that $U_+ = \sqrt{8/\lambda}$, where $\lambda$ is the friction factor, and thus $f_1(\cdot)$ is a discharge function of the dimensionless driving force $R_+$ at constant $S$ and $H^T$. However, while these general relations bear some resemblance to the well-known resistance correlations for turbulent flow in pipes, the specific forms of the functions are unlikely to be similar. Omitted from the list of independent variables is one which contains a characteristic modulus reflecting the RBC-membrane elasticity. The deformation of RBCs is a consequence of the flow driven by the imposed pressure gradient, which is already present in $R_+$. In a mono-disperse model with parameters fitted to represent normal human blood an elasticity parameter will be needed for comparisons with abnormal human blood or that of other species.

In the limit $H^T = 0$, Poiseuille’s law determines the discharge law to be $U_+ = R_+ / 4$. For blood flow the common measure of flow resistance is the apparent viscosity $\eta_{\text{app}}$, defined via Poiseuille’s law. In terms of dimensionless variables the apparent viscosity is expressible as $\eta_{\text{app}}/\mu = R_+/(4U_+)$. The familiar Fahraeus-Lindqvist plot (Fahraeus & Lindqvist 1931; Pries et al. 1992) represents experimental data of $\eta_{\text{app}}/\mu$ at constant $H^D$ as a function of dimensional $D$, which for a mono-disperse suspension is equivalent to $S$. A goal of simulations of RBC suspensions in tube flow is the determination of the validity of the functional dependencies implied by equation (3.5). The dimensionless functional relations proposed in equation (3.5) are shown in figure 13 as relative apparent viscosity and $H^D/H^T$ plotted against $D$ and in figure 14 as $U_+$ versus $R_+$. The solid curves in figure 13 and the dashed lines in figure 14 were calculated from the correlations of Pries et al. (1992).
Figure 14. Dimensionless bulk velocity $U_+$ as a function of friction Reynolds number $R_+$ at (a) $H^T = 0.3$ and (b) $H^T = 0.45$. The dashed lines are calculated from correlations of Pries et al. (1992), while DPD simulations are shown by filled symbols for $D = 10 \mu m$ (triangle), $D = 20 \mu m$ (diamond), $D = 40 \mu m$ (gradient), $D = 100 \mu m$ (square), and $D = 150 \mu m$ (circle).

Figure 14 shows that for the larger tubes $D > 100 \mu m$ flow resistance at $H^T = 0.3$ is independent of $S$, whereas for smaller tubes $S$ must be retained as an independent variable in the resistance function of equation (3.5). This is consistent with the viscosity distributions of figure 11 and with other distributions of single RBC properties shown in figures 6, 7, and 8. The correlations of Pries et al. (1992) omit dependence on the driving pressure gradient. The dimensionless equivalent for the resistance correlations is

$$\eta_{app}/\mu = R_+/(4U_+) \approx f_4(S, H^T).$$

Unlike the Poiseuille-flow solid line for the Newtonian plasma, the dashed lines in figure 14 may not extrapolate to the origin, since otherwise the functional relation for the resistance in equation (3.6) would become exact. The slope of each line in figure 14 is determined by a point on the relative apparent-viscosity curve in figure 13(a), while equation (3.6) is an approximate statement of functional dependence. In Pries et al. (1992) the relative apparent viscosity correlation with $D$ is derived from the data taken from a number of sources. It is not clear whether the considerable scatter is due to the variability inherent in measurements made in different laboratories on a fragile material, or due to the omission of the pressure gradient as a dependent variable. The omission of the driving pressure gradient from the correlation of $H^D/H^T$ is consistent with equation (3.6). It is well-known that in turbulent flow at high Reynolds numbers certain hydraulic coefficients become constant, such as the friction factor at constant finite pipe-roughness or the drag coefficient of bluff bodies. It appears that for tube-flow of blood suspensions the ratio $\eta_{app}/\mu$ is an essentially constant hydraulic coefficient over the range of physiological low friction Reynolds numbers. (The values of $R_+$ in figure 14 are well below the turbulence transition of $R_+ \approx 65$ in pipe flow of a Newtonian fluid.)

3.4. Newtonian fluid approximation with velocity-slip boundary condition

In the simulation of flow in the large vessels blood is taken to be a Newtonian fluid with no-slip on the vessel walls. This assumption becomes increasingly tenuous in the micro-circulation for vessel diameters less than about $200 \mu m$. The complexities of blood flow in blood-vessel networks have been reviewed by Popel & Johnson (2005). Flow in
long straight tubes is obviously an idealization of these systems, but it can be realized in fairly precise quantitative experiments to provide insights into the in vivo scenario. The DPD simulations of this work are computationally expensive, and this motivates our investigation to extend the continuum model to allow an approximate description of blood flow in tubes with diameters smaller than 200 µm. For gases confined in narrow channels of decreasing size the breakdown of the continuum model manifests itself as jump conditions at the boundaries. For the velocity the adherence condition changes to slip-flow along channel walls. Here, we present a very simple, four-parameter slip-flow model for blood suspensions flowing in small tubes of diameter $D$ driven by a pressure gradient $dP/dx$. Two additional parameters, namely the tube hematocrit $H^T$, and the plasma viscosity $\mu$, also need to be specified. With the four specified parameters the correlations of Pries et al. (1992) yield the apparent viscosity $\eta_{app}$ and hematocrit ratio $H^D/H^T$. The latter allows the CFL thickness to be estimated as $\delta'$ in equation (2.5). If available, it may be preferable to employ experimental values of $\delta$ and $\eta_{app}$.

Within the CFL the fluid is taken to be Newtonian with the plasma viscosity $\mu$. Under the action of the prescribed pressure gradient the velocity $u_{cf}(r)$ is the Poiseuille field,

$$ u_{cf}(r) = \frac{1}{4\mu \frac{dP}{dx}} (R^2 - r^2), \quad R - \delta < r < R. \quad (3.7) $$

The first step employs the mean velocity $U_0$ and the centroid position $R_0$ of $u_{cf}(r)$ within the CFL defined by the integrals,

$$ \int_{R-\delta}^{R} 2\pi u_{cf}(r)r dr = \pi \delta(2R - \delta)U_0, \quad (3.8) $$

$$ \int_{R-\delta}^{R} 2\pi u_{cf}(r)r^2 dr = \pi \delta(2R - \delta)R_0U_0. $$

The flow beyond $R_0$ is “skimmed off”, and hence the tube radius is effectively reduced to $R_0$ with a slip velocity of $u_{cf}(R_0)$ along the adjusted boundary. However, to conserve the total volumetric flow in the reduced tube the flow skimmed off is accounted for as a uniform flow across the tube. Hence the slip velocity is adjusted as follows,

$$ U_s = u_{cf}(R_0) + \phi R_0 / \pi R_0^2, \quad \phi R_0 = \int_{R_0}^{R} u_{cf}(r)2\pi r dr. \quad (3.9) $$

Within the reduced tube the fluid is also taken to be Newtonian, but with ‘effective’ viscosity $\eta_{eff}$. The skimmed velocity field $u_{sk}(r)$ becomes

$$ u_{sk}(r) = \frac{1}{4\eta_{eff} \frac{dP}{dx}} (R_0^2 - r^2) + U_s, \quad 0 < r < R_0. \quad (3.10) $$

The total flow rate $Q$ is determined from Poiseuille’s law with $\eta_{app}$ given by the Pries et al. (1992) correlation, or by integration of the DPD simulation velocity profiles. The total flow rate in the reduced tube is the integral of $u_{sk}(r)$ across the reduced section, and hence $\eta_{eff}$ is determined by the equality,

$$ Q = \frac{\pi R^4}{8\eta_{app}} \frac{dP}{dx} = \frac{\pi R_0^4}{8\eta_{eff}} dP/dx + \pi R_0^2 U_s, \quad (3.11) $$

The simple velocity-slip model we propose can be summarized as follows:

- Specify the values of tube diameter $D$, pressure gradient $\frac{dP}{dx}$, tube hematocrit $H^T$ and the blood plasma viscosity $\mu$.
- With the above four parameters above, obtain the apparent viscosity $\eta_{app}$ and hematocrit $H^T$. 

Blood Flow in Small Tubes
Figure 15. Velocity profiles for (a) \( D = 20 \, \mu m \) and (b) \( D = 100 \, \mu m \) at \( H^T = 0.3 \). Red squares denote DPD simulation results displayed in figure 1. The dashed blue curves show the profiles of the slip-velocity model with the wall-slip boundary condition of equations (3.10) and (3.9). The vertical dashed lines give the position of the CFL and the radius \( R_0 \) (equation (3.8)) of the adjusted boundary. The dash-dotted green parabola is the no-slip velocity profile for a Newtonian fluid with apparent viscosity calculated from Poiseuille’s law to match the flow rate of the DPD simulation.

tocrit ratio \( H^D/H^T \) from the the correlation of Pries et al. (1992). The latter allows the CFL thickness to be estimated by Eq. (2.5).

- In the CFL region, compute the mean velocity \( U_0 \) and the centroid position \( R_0 \) by Eq. (3.8).
- Compute the slip velocity \( U_s \) by Eq. (3.9) using the centroid position \( R_0 \).
- With \( U_s \) and \( R_0 \), approximate the blood velocity profile by Eq. (3.10).

In figure 15 the slip-velocity model in the reduced tubes is compared with the Newtonian no-slip profiles calculated with \( \eta_{app} \) and with the DPD simulation velocity profiles presented above for the original tubes. Table 2 summarizes the results for all of the tubes of the simulations. The slip-velocity model and the Newtonian no-slip model are denoted as NewtonianS and NewtonianNS respectively. The CFL thicknesses are the direct values \( \delta \) shown in figure 10 and also given in table 1. The viscosity value for Poiseuille flow with no slip (NewtonianNS) is the apparent viscosity which yields the flow rate \( Q \) of the DPD simulated flow. Thus, the viscosity is essentially the \( \eta_{app} \) defined by Pries et al. (1992), since the latter is accurately predicted by the DPD model as shown in figure 13(a). For the slip-model (NewtonianS) the errors in \( U_m \) range from about 5% to 14% as the diameter decreases. It was shown above that flow of the model blood suspension in 20 \( \mu m \) tubes does not satisfy the principle of local action, but an economic continuum calculation with errors of 10% may be acceptable alternative to an expensive mesoscopic simulation. When only the flow rate is required, then the NewtonianNS model will yield the correct result even though \( U_m \) will be greatly overestimated. It might be thought that improved estimates of \( U_s \) and \( R_0 \) are achievable by use of expansion (3.4) in the CFL, since figure 12 shows the coefficients for the larger tubes to be only weakly dependent on tube size. However, the result would be a smaller \( U_s \), and hence a larger error in \( U_m \). Improved accuracy calls for improved velocity approximations in both the CFL and the main flow, which in turn calls for the specification of additional parameters.

Since the ultimate goal of these models is their capacity to simulate blood flow in the

Table 2. Flow rate \( Q \) and maximum flow velocity \( U_m \) calculated in DPD simulations and with the Newtonian\textsuperscript{S} and Newtonian\textsuperscript{NS} models at \( H_T = 0.3 \). The slip velocity \( U_s \) for the Newtonian\textsuperscript{S} model is also shown. For each tube size \( D \) the pressure gradient \( \frac{\partial p}{\partial x} \) is specified, and the flow rates are set to be equal to determine the effective viscosity by equation (3.11). The tabulated values for \( D = 20 \) and 100 \( \mu m \) correspond to the velocity profiles of figure 15.

microcirculation, the next step in their development is their extension to tapered tubes with non-circular varying cross-sections.

4. Summary and Conclusions

This work has presented results and analysis of DPD simulations of Poiseuille flow of blood suspensions in small tubes in the size-range 10 – 150 \( \mu m \). The modeled suspension of mono-dispersed red-blood cells used here was previously applied in the simulation of homogeneous plane-shear flow by Fedosov \textit{et al.} (2011). There it was demonstrated to successfully predict the measured Couette viscosity of whole human blood and washed erythrocyte suspensions. The important distinction between Poiseuille flow and homogeneous plane-shear flow is the cross-stream stress gradient whose effects are analyzed and compared with available experimental measurements. Below we summarize the main findings of this work.

- The simulations yield particle variables whose statistical averages are the continuum field variables (e.g., velocity, hematocrit), which are presented above as radial distributions across tube sections. The non-uniform cell number-density profiles reveal the main effects of the cross-stream stress gradient to be a cell-free-layer (CFL) near the tube wall and a concentration peak near the centerline. The response of the suspended cells to the variable shear field is derived from their gyration tensors to measure cell asphericity, deformation, and orientation relative to the shear planes. The smoothness of the velocity profiles allows the calculation of strain-rate distributions by numerical differentiation. For the larger tubes, these show a region of linear strain rate variation beyond the CFL where the hematocrit is nearly constant, whereas for the smaller tubes the strain-rate
profiles are non-linear over the whole section. The imposed linear shear-stress distributions and the calculated strain rates yield local viscosity distributions, which show an abrupt transition at the edge of the CFL. The transition values of viscosity and shear rate are then used to scale the viscosity and other variables to demonstrate their similarity for the larger sizes and increasing departures from similarity with diminishing diameter. In the size range of similar viscosity the curves are in good agreement with experimental Couette viscosity correlations evaluated at the local shear rate and hematocrit.

- The CFL thickness is the most important measure of non-uniformity, and is defined as the average edge position of cell surfaces nearest to the wall. Motivated by boundary layer concepts, two alternative measures of CFL thickness were investigated which appear to be good approximations for the average edge position. They provide useful estimates in terms of the tube hematocrit $H^T$, the discharge hematocrit $H^D$, and the ratio maximum-to-bulk velocities.

- For blood flow in tubes the choice of dimensionless groups to represent resistance and other global variables is motivated by the dimensional analysis of turbulent pipe flow. The introduction of the friction Reynolds number $R_+$ and the expression for the apparent viscosity $\eta_{app}/\mu = R_+(4U_+/\mu)$ provides some insight into the evident success of the dimensional correlations of Pries et al. (1992). For the flow resistance measured as apparent viscosity, these contain no explicit dependence on the driving force which is consistent with $\eta_{app}/\mu$ being a function only of the size ratio $S$ and the tube hematocrit $H^T$. Such response is reminiscent of the constancy of the friction factor in rough pipes at high Reynolds numbers, and the similar behavior of the drag coefficient for bluff bodies. The linearity of $\eta_{app}/\mu$ with respect to $R_+$ is a consequence of the low Reynolds numbers of blood flow in small tubes.

- The most important finding of this investigation is that for a blood suspension flowing in small tubes, and hence in small vessels, the description of the stress as a continuum, whether homogeneous or heterogeneous, fails once the tube size decreases to about 100 $\mu m$. This has been demonstrated above with the viscosity distributions of figure 11 and other flow properties including RBC asphericity, deformation, and orientation in figures 6, 7, and 8.

- The computationally costly DPD simulations described above have revealed precise information on the non-continuum character of blood suspension flow in small tubes. However, such computations are not viable for the more complex flows of the micro-circulation, and it remains a goal to extend to smaller vessels the continuum methods employed to simulate blood flow in larger vessels. The velocity-slip model of this work attempts to show that the Navier-Stokes description of the stress combined with slip at the wall yields fairly accurate velocity fields in the main flow. Most importantly this result is achieved with the specification of only two parameters, namely, the plasma viscosity $\mu$ and $H^T$, in addition to diameter and driving pressure gradient. Whether the approximation can be extended to tapered tubes with junctions and to unsteady flow is a task for future investigation.

Appendix A. Dissipative particle dynamics

Our simulations employ Dissipative Particle Dynamics (DPD), a mesoscopic simulation method (Hoogerbrugge & Koelman 1992; Espanol & Warren 1995), where each DPD particle represents a virtual cluster of atoms or molecules rather than an individual atom. Different from the Molecular Dynamics (MD) method, additional dissipative and random forces are included in the particle interactions due to the eliminated degrees
Blood Flow in Small Tubes

of freedom during the coarse-graining procedure (Lei et al. 2010). The DPD governing equations are summarized below.

A.1. DPD governing equations

The standard DPD formulation (Hoogerbrugge & Koelman 1992) with the motion of each particle governed by

\[ \frac{dr_i}{dt} = v_i dt, \]
\[ \frac{dv_i}{dt} = \left( F_C^i dt + F_D^i dt + F_R^i \sqrt{dt} \right)/m, \]  

(A 1)

where \( r_i, v_i, m \) are the position, velocity, and mass of the particle \( i \), and \( F_C^i, F_D^i, F_R^i \) are the total conservative, dissipative and random forces acting on the particle \( i \), respectively. Under the assumption of pairwise interactions the DPD forces are given by the sum of the pair interactions with the surrounding particles as follows

\[ F_{C}^{ij} = \begin{cases} a(1.0 - r_{ij}/r_c)e_{ij}, & r_{ij} < r_c \\ 0, & r_{ij} > r_c \end{cases} \]  

(A 2)

\[ F_{D}^{ij} = -\gamma w^D(r_{ij})(v_{ij} \cdot e_{ij})e_{ij}, \]
\[ F_{R}^{ij} = \sigma w^R(r_{ij})\xi_{ij}e_{ij}, \]  

(A 3)

where \( r_{ij} = r_i - r_j, r_{ij} = |r_{ij}|, e_{ij} = r_{ij}/r_{ij}, \) and \( v_{ij} = v_i - v_j, r_c \) is the cut-off radius beyond which all interactions vanish. The coefficients \( a, \gamma, \sigma \) represent the strength of the conservative, dissipative and random force, respectively. The last two coefficients are coupled with the temperature of the system by the fluctuation-dissipation theorem (Español & Warren 1995) as \( \sigma^2 = 2\gamma k_B T \). Here, \( \xi_{ij} \) are independent Gaussian random variables with zero mean and unit variance. The weight functions \( w^D(r) \) and \( w^R(r) \) are defined by

\[ w^D(r_{ij}) = \left[w^R(r_{ij})\right]^2, \]
\[ w^R(r_{ij}) = (1.0 - r_{ij}/r_c)^k, \]  

(A 4)

where \( k = 1.0 \) in the standard DPD method; however, other values of \( k \) have been used to increase the viscosity of the DPD fluid (Fan et al. 2006). In the current work we chose \( k = 0.25 \).

A.2. Multiscale red blood cell (MS-RBC) model

The average equilibrium shape of a RBC is biconcave as measured experimentally (Evans & Skalak 1980). The surface area and volume of this RBC are equal to 135 \( \mu m^2 \) and 94 \( \mu m^3 \), respectively. The RBC membrane is modeled by a network of springs which corresponds to a triangulation on the membrane surface (Discher et al. 1998; Fedosov et al. 2010a, c). For each single cell, the free energy is defined by

\[ V_{rbc} = V_s + V_b + V_a + V_v, \]  

(A 5)

where \( V_s \) represents the visco-elastic bond interaction between the cell vertices such that proper membrane mechanical properties can be imposed. \( V_b \) represents the bending energy of the cell membrane. \( V_a \) and \( V_v \) represent the area and volume constraints to mimic the incompressibility of the lipid bilayer and the intracellular cytosol. More details on the RBC model and the scaling between the model and the physical units can be found in Fedosov et al. (2010a) and Fedosov et al. (2010c).
Table 3. Parameters used for the pressure-driven blood flow for different diameters and $H^T$ values. The cases with the superscript $*$ were used for a sensitivity study where adhesion interactions were applied between the cells.

A.3. Simulation parameters

The viscosity of blood plasma was taken to be $\mu = 1.2 \times 10^{-3} \text{ Pa} \cdot \text{s}$, the length, time and force units are

$$1\tau = 3.608 \times 10^{-4} \text{s}$$
$$1 r_c = 0.97 \mu \text{m}$$
$$1 f_{DPD} = 4.673 \times 10^{-14} \text{N}$$
$$1 P_{a_{DPD}} = 4.964 \times 10^{-2} \text{Pa}$$

The parameters we use for the different cases are shown in table 3.
